ABSTRACT

Fetal macrosomia is associated with a number of health complications for both mother and infant in the immediate, short, and long-term. Maternal obesity and excessive gestational weight gain (GWG) have long been associated with fetal macrosomia, however the impact of maternal lifestyle factors such as dietary intake and energy balance, in combination with the timing and composition of weight gain, have been less studied. It is also clear that although maternal obesity and excessive GWG increase the risk of fetal macrosomia independently, the risk is magnified with the presence of both risk factors, suggesting that interventions to control GWG may be particularly important for obese women. Association studies examining the relationship between fetal nutrient availability, epigenetic modifications, and infant anthropometrics are also required. This review provides an overview of the current evidence examining the role of maternal lifestyle factors on the prevalence of fetal macrosomia and identifies areas where further research is required in order to inform the design of appropriate intervention strategies.

Keywords: Birth weight, body composition, gestational weight gain (GWG), macrosomia, maternal obesity.

INTRODUCTION

Birth weight is a key determinant of infant health, which appears to be determined by a complex interaction of maternal and fetal factors. These probably include maternal genetic, environmental, and lifestyle factors, in conjunction with fetal genetic and intrauterine environmental factors. Macrosomia is generally defined as a birth weight >4,000 g or 4,500 g, irrespective of gestational age,1 while large for gestational age (LGA) is defined as a birth weight >90th percentile as per gestational age.2 Excessive fetal growth results in increased immediate, short, and long-term risks for both mother and infant. Macrosomia increases the risk of complications during delivery such as birth asphyxia, shoulder dystocia, and increased incidence of delivery via caesarean section, which carries its own adverse risks to both neonate and mother.3 Furthermore, higher birth weight is also associated with increased risk of obesity4 and metabolic syndrome5 into childhood, which have serious long-term health consequences.

Numerous maternal factors such as body mass index (BMI), gestational weight gain (GWG), diet, physical activity, and the development of gestational diabetes have all been shown to impact infant birth weight. However, previous studies have tended to examine these factors individually, and their interaction even less so. The purpose of this review is to critically appraise the current literature and highlight areas where further research is required to inform appropriate maternal intervention strategies, with the aim of improving neonatal health.

MATERNAL WEIGHT

When examined individually, high maternal pre-pregnancy BMI tends to be strongly associated with an increased risk of macrosomia. Numerous studies have reported women classified by their BMI as obese to be at a significantly greater risk of macrosomia compared with women classified as having a healthy weight,6,7 with risk increasing as BMI increases beyond the healthy range.8 A recent systematic review and meta-analysis
conducted by Gaudet et al. showed a positive relationship between maternal obesity and fetal overgrowth as defined by birth weight ≥4,000 g, ≥4,500 g, and ≥90th percentile for gestational age.

Similarly, excessive GWG has been shown to increase risk of macrosomia. Although it appears that both maternal obesity and excess GWG independently increase the risk of macrosomia, the interaction between the two factors is less clear. Crane et al. conducted a retrospective cohort study evaluating the effects of GWG on maternal and neonatal outcomes in different BMI classes. In keeping with findings from previous studies they observed that overweight and obese mothers were significantly more likely to give birth to a macrosomic infant (birth weight ≥4,000 g and adjusted for gestational age) and also more likely to gain excess weight than healthy weight mothers. However, when the impact of GWG on risk of macrosomic infant was examined by BMI class, risk increased with excess GWG for all BMI classes suggesting that when excessive GWG does occur, the risk of macrosomia increases regardless of pre-pregnancy BMI. A major limitation of this study was that it was retrospective, and so pre-pregnancy BMI or GWG data were missing for 47.8% of the study participants. Nohr et al. conducted a similar study reporting that BMI ≥4,500 g, and ≥90th percentile for gestational age. Prevention of excess GWG in women of healthy pre-pregnancy BMI is therefore also important, just as in overweight or obese mothers. In 2009, the Institute of Medicine (IOM) published a new set of guidelines on GWG to replace those previously published in 1990 and now make recommendations based on pre-pregnancy BMI category for total and rate of weight gain.

It has been suggested that birth weight and early childhood growth patterns can lead to a predisposition to childhood obesity, with the potential to persist into adolescence and adulthood. In a diverse sample of women from the USA, inadequate GWG, when compared with adequate weight gain, was associated with significantly increased odds of infants being born small for gestational age (SGA), while excessive gain was significantly associated with decreased odds of SGA and more than doubled the risk of LGA. Excessive GWG also significantly increased the risk of child overweight or obesity (BMI ≥85th percentile) when followed up between the ages of 2 and 20 years. For overweight and obese women, predicted probabilities of LGA newborns and childhood overweight were higher than those for underweight or healthy weight women, regardless of GWG. Increased GWG was significantly associated with increased probability of LGA and an overweight child across all BMI groups. Similarly, a retrospective cohort of 499 mother–child dyads observed that maternal morbid obesity (BMI ≥40 kg/m²) was significantly associated with infant birth weight and weight for height at 12 months of age. At 12 months of age these effects were sustained, with infants of morbidly obese mothers exhibiting an 8.4% higher weight for height percentile compared with infants of mothers with a BMI of 25 kg/m². Infants born to mothers with a healthy BMI but with excess GWG normalised their growth by 12 months of age.

These findings suggest that babies born to women in all BMI categories are at risk of increased birth weight and elevated weight during early life as a result of excessive GWG, but that overweight and obese women are of particular concern, as their risk appears to be amplified. Future studies,
particularly of a prospective nature, should therefore focus on this group of women in order to develop a wider understanding of lifestyle factors that contribute to excess GWG.

**MATERNAL BODY COMPOSITION**

Although BMI is widely used to provide estimates of body composition, it is not without its limitations. Prentice and Jebb\(^{20}\) propose that obesity should be defined as the excess accumulation of body fat, whereas BMI identifies the presence of excess body weight, which also reflects lean body mass. Krentz et al.\(^{21}\) compared birth weight outcomes for women with the same BMI, but two different heights in a retrospective cohort study. They observed differences in birth weights and birth weight classification by gestational age between groups, which once again provided evidence to suggest the limited utility of BMI as a predictor of neonatal outcomes. In addition, GWG is typically reported as a single measure of mass gained during pregnancy, with the individual effects of fat mass and fat-free mass gains left undefined. It therefore seems prudent to examine the contributions of changes to estimated maternal fat mass and fat-free mass on pregnancy outcomes, in addition to total GWG and maternal obesity defined by BMI.

As might be expected, maternal weight, fat-free mass, and fat mass increased between 28 and 37 weeks gestation in a recent prospective cohort study examining maternal body composition. However, birth weight significantly correlated with maternal fat-free mass and not fat mass.\(^{22}\) In a similar study, fat-free mass, but not fat mass, was also a significant predictor of birth weight and after adjustment for confounding variables, mothers in the highest fat-free mass quartile were at significantly higher risk of infant macrosomia, compared with mothers in the lowest quartile.\(^{23}\) However, this study measured body composition only in the first trimester. Butte et al.\(^{24}\) divided GWG into fat mass, fat-free mass, total body water, and protein gains as assessed at 9, 22, and 36 weeks of gestation. Infant birth weight was found to correlate significantly with fat-free mass \((r=0.39, p=0.003)\) and total body water \((r=0.37, p=0.006)\), but not fat mass \((r=0.05, p=0.76)\). These studies suggest that fat-free mass, and not fat mass mediates an increase in infant birth weight. It is hypothesised that these positive associations between maternal fat-free mass and infant birth weight may be due to maternal plasma volume expansion,\(^{25}\) which in turn is influenced by maternal hormonal changes.\(^{26}\)

Forsum et al.\(^{27}\) addressed the hypothesis that maternal body fat stimulates fetal growth and fat deposition. In a small, observational study they assessed infant subcutaneous adipose tissue volume *in vivo* using magnetic resonance imaging, while maternal body composition was assessed using a two-compartment model based on total body water. It was observed that maternal total body fat before pregnancy and at 32 weeks gestation was significantly and positively correlated with infant birth weight, while in infants, birth weight positively correlated with subcutaneous adipose tissue. Further studies examining the effects of maternal body composition on neonatal body composition and incidence of macrosomia are therefore required in order to fully understand the relationship between the composition of GWG and infant birth size.

**TIMING OF GESTATIONAL WEIGHT GAIN**

Although the influence of total GWG during pregnancy has been well documented, the timing of overnutrition and subsequent weight gain has not been examined as thoroughly. This could be an important factor in the design of any intervention studies. Davenport et al.\(^{28}\) evaluated whether the timing of excessive GWG in pregnant women following current healthy living guidelines affected neonatal adiposity at birth in their prospective cohort study. The cohort was retrospectively grouped according to IOM guidelines\(^{11}\) by weight gain in the first and second halves of pregnancy. Infants born to women who exhibited excessive GWG during the first half of pregnancy exhibited greater birth weight, crown-heel length, and excessive neonatal body fat compared with infants born to women who exhibited appropriate GWG in the first half of pregnancy. These differences remained significant after controlling for BMI, total GWG, maternal age, gestational age, and neonatal sex. Farah et al.\(^{22}\) conducted a longitudinal prospective observational study which observed that birth weight was significantly correlated with GWG before the third trimester \((r=0.163, p=0.027)\) but not with total or third trimester GWG. These studies suggest that neonatal adiposity is potentially more strongly influenced by timing of GWG than total GWG, suggesting a direct link between the early
intrauterine environment and subsequent neonatal adiposity. However, the data on timing of GWG and its influence on neonatal weight and adiposity is limited. Studies examining weight change during pregnancy with frequent assessments are therefore required in order to increase our understanding of the mechanism by which maternal obesity and GWG influence infant birth weight and body composition.

**GESTATIONAL DIABETES MELLITUS**

Gestational diabetes mellitus (GDM) is a common metabolic complication of pregnancy, defined as glucose intolerance with first onset or recognition during pregnancy. GDM is most frequently observed amongst overweight or obese women as these women are more likely to exhibit impaired glucose tolerance and decreased insulin sensitivity before and during pregnancy when compared with women of a healthy weight. Infants born to women with GDM are often characterised by excessive fetal growth and subsequently tend to be at increased risk of macrosomia. However, even in the absence of increased body mass, studies have shown that infants born to mothers with GDM exhibit increases in fat mass, but not fat-free mass when compared with women with normal glucose tolerance. Results from the Hyperglycaemia and Adverse Pregnancy Outcome (HAPO) study observed an increase in neonatal adiposity associated with increasing maternal glucose concentrations, less than those used to define GDM. Physical activity has also been shown to influence glucose metabolism and transport via insulin-independent pathways and has been associated with a decreased incidence of GDM in epidemiological studies.

**MATERNAL ENERGY INTAKE AND EXPENDITURE**

Clearly, nutritional status prior to and during pregnancy is essential for the growth and development of the fetus, with excessive GWG and adverse pregnancy outcomes also largely influenced by dietary intake either as nutrient excess, nutrient deficiencies, or by indirectly influencing the intrauterine environment. A study by Knudsen et al. supports the theory that maternal glucose metabolism may impact fetal growth. They examined the associations between maternal glycaemic load, GWG, birth weight, and risk of LGA neonate as part of the Danish National Birth Cohort. They observed that the risk of LGA neonate increased by 14% for the highest glycaemic load quintile, compared with the lowest quintile. A randomised controlled trial examining the impact of a low glycaemic index diet on neonatal anthropometry observed a decrease in neonatal thigh circumference for the intervention group when compared with a control group, although no differences were observed for any skinfold measurements, nor head, abdominal, and mid-upper arm circumferences.

In a prospective study, GWG was significantly and positively associated with energy intake and energy-adjusted intakes of lipids from animal origin and protein, while a significant inverse association was observed between carbohydrate intake and GWG, but these were not significantly related to birth size. Olsen et al. observed that milk consumption during pregnancy was inversely associated with SGA, and directly associated with LGA and mean birth weight. Women consuming ≥6 glasses of milk/day had increased risk of LGA infants when compared with women who reported no milk consumption. When fat and protein intakes from dairy products (excluding cheese and ice cream) were examined, no association between birth weight and fat intake was found, while a positive association between protein intake and birth weight was observed. The authors proposed that the positive association between milk consumption and birth weight is driven by the presence of insulin-like growth factor 1 in both low-fat and whole-milk products. Montpetit et al. examined the contribution of pre-pregnancy BMI, energy intake, and physical activity as determinants of GWG and infant birth weight. Energy intake was the only significant predictor of infant birth weight. Steps per day were inversely associated with GWG, although when pre-pregnancy BMI was added to the model, steps were no longer significant and BMI remained the only significant variable.

A study conducted in the USA observed decreases in birth weight and LGA births between 2000 and 2005, trends which did not appear to be explained by routinely recorded maternal characteristics. The authors hypothesised that other maternal characteristics such as maternal diet, physical activity, or socioeconomic factors may have contributed to the trends observed and called for detailed studies of smaller populations to explore the role of these factors.
Furthermore, the rapidly expanding field of epigenetic epidemiology has observed numerous associations between fetal nutrient availability and epigenetic modifications. Differences in the methylation status of candidate genes have been observed in relation to fetal growth and later childhood adiposity. However, human studies examining specific intraterine nutritional exposures and subsequent adiposity at birth and during childhood are scarce. Studies of an observational and epigenetic nature are therefore essential for increasing our understanding of how nutritional exposures influence GWG and infant phenotypic outcomes.

**CONCLUSION**

It is important to gain an understanding of the factors influencing neonatal anthropometric outcomes, as macrosomic infants with or without excess adiposity at birth have been shown to be at increased risk of adverse consequences such as insulin resistance, metabolic syndrome, and childhood obesity. As observed in the current literature, there is consistent evidence to suggest that maternal obesity and excess GWG alongside GDM contribute to increased risk of adverse neonatal anthropometric outcomes; hence current pregnancy interventions are already aiming to reduce the prevalence of these risk factors. However, maternal obesity and GWG are broad outcome measures. Recent studies suggest maternal body composition and timing of GWG may influence infant anthropometrics independently of maternal BMI and total GWG, which may offer an increased understanding of the mechanisms by which maternal obesity and GWG influence neonatal anthropometric outcomes. At present, data in this area is limited and there is also a lack of recent prospective studies examining the effects of GWG by BMI according to the most recent IOM recommendations.

BMI: body mass index; LGA: large for gestational age; GDM: gestational diabetes mellitus; GWG: gestational weight gain; N/A: not applicable.
Maternal diet and energy balance during pregnancy undoubtedly influence GWG and subsequent anthropometric outcomes for offspring. However, despite a wealth of studies linking maternal energy intake to GWG, and maternal dietary glucose intake to neonatal anthropometry,26,27 few studies have examined the impact of other nutrients in the maternal diet, nor energy balance together with physical activity. Studies examining nutritional exposures during pregnancy and epigenetic modifications in offspring are also required.30

The contributions of various maternal lifestyle factors to fetal macrosomia from the current literature are summarised in Table 1. As discussed, however, there are gaps in the current literature, as well as conflicting findings. It is therefore necessary to examine further the independent and moderating effects of maternal dietary intake, physical activity, and the timing and composition of GWG on neonatal anthropometric outcomes in future studies. Such studies could provide a more complete picture of the maternal lifestyle factors contributing to GWG, neonatal body composition, and potentially future offspring health, thus allowing health professionals to develop suitable and effective interventions to improve birth and health outcomes for both mother and infant. In the meantime, pregnant women should be advised to adhere to IOM guidelines for weight gain11 and offered nutritional support if necessary. Particularly close attention should be paid to women entering their pregnancy with a BMI ≥30, as offspring of these women appear to be at increased risk of macrosomia, regardless of the contribution of other potential risk factors yet to be investigated.
